

Vasilis Syrgkanis¹

Summary

- We estimate heterogeneous causal effects in the presence of unol confounders with the aid of a valid instrument
- We build robust methods that leverage arbitrary machine learnin account for heterogeneous treatment effects and compliance
- We partnered with TripAdvisor to apply these methods to an A/B intent-to-treat structure
- This work resolves an open question in the literature¹

TripAdvisor's Questions

- What is the *causal effect* of becoming a member on TripAdvisor on downstream activity on the webpage?
- How does that effect vary with observable characteristics of the user?
- Useful for understanding the quality of membership offering, improvements, and targeting

Standard approach: Let's run an A/B test **Problem:** We cannot enforce the treatment

Membership is an action that requires user engagement!

Formal Model

- $T \rightarrow \text{treatment}, e.g. user membership$
- $Y \rightarrow$ outcome, e.g. webpage activity
- $X \rightarrow$ features that capture heterogeneity, e.g. user features
- $Z \rightarrow$ instrumental variable: a variable that affects the treatment T but does not affect the outcome Y other than through the treatment e.g. assignment in A/B test

Structural equations:

$$Y = \theta(X) \cdot T + f_0(X) + e$$
$$T = g_0(X, Z) + \eta$$

where $\mathbb{E}[e \mid X, Z] = 0.$

Limitations of Typical IV Methods

- Cannot estimate a complex $\theta(X)$
- Do not account for compliance heterogeneity
- Do not leverage Machine Learning estimation techniques
- **Example:** Let $\tilde{Y} = Y \mathbb{E}[Y|X], \tilde{T} = T \mathbb{E}[T|X], \tilde{Z} = Z \mathbb{E}[Z|X], \beta_0(X) = \mathbb{E}[\tilde{T}\tilde{Z}|X]$ (2) proposes the following robust estimate of the average treatment effect $\hat{\theta}$:

$$\mathbb{E}[\theta(X)] = \hat{\theta} = \frac{\mathbb{E}[\tilde{Y}\tilde{Z}]}{\mathbb{E}[\tilde{T}\tilde{Z}]}$$
 (ATE)

Since $\hat{\theta} \mathbb{E}[\tilde{T}\tilde{Z}] = \mathbb{E}[\theta(X)\tilde{T}\tilde{Z}]$ in the limit, then:

$$= \frac{\mathbb{E}[\theta(X)\beta_0(X)]}{\mathbb{E}[\theta(X)\beta_0(X)]}$$

$$\mathbb{E}[\beta_0(X)]$$

which is **consistent only if** $\theta(X)$ is constant (no heterogeneity) or $\theta(X)$ and $\beta_0(X)$ are independent (uniform compliance)!

Machine Learning Estimation of Heterogeneous Treatment Effects with Instruments

DINIV AIgui
Doubly Robust Instrumental Variable (DRIV) Treat
1. Consider the compliance score ³ :
$\Delta(X) = (2Z - 1) \frac{\mathbb{P}(T = 1 Z = 1,)}{-1}$
Define the following residuals:
$\widetilde{Y} = Y - \mathbb{E}[Y X], \widetilde{T} = T - \mathbb{E}[T]$
2. Estimate preliminary $\widehat{\theta}(X)$:
$\widehat{\theta} = \arg\min_{\theta(\cdot)} \mathbb{E}\left[\left(\widetilde{Y} - \theta\right)\right]$
3. Estimate robust final $\theta(X)$:
$\min_{\theta(\cdot)} \mathbb{E}\left[\left(\widehat{\theta}(X) + \frac{\widetilde{Y} - \widehat{\theta}(X)}{\Delta(X)} \right) \right]$
* More generally, when T and Z are arbitrary and a
$\min_{\theta(\cdot)} \mathbb{E}\left[\left(\widehat{\theta}(X) + \frac{(\widetilde{Y} - \widehat{\theta}(X))}{\widehat{\beta}(X)} \right) \right]$
where $\beta_0(X) = \mathbb{E}[\tilde{T}\tilde{Z} X]$ and $\tilde{Z}/\hat{\beta}(X)$ is known as
Reduction to a Set of Regression/ Classification St

In the above algorithm, the steps marked with \star , \star are classifications and regression tasks, respectively. Benefits of this approach:

- **Statistical and computational benefits** of modern ML approaches (forests, regularized linear models, SVM, DNNs etc.)
- **Cross-validation** for model selection and hyperparameter tuning
- **Interpretability** of estimated models (SHAP, Lime, Influence functions)

Properties of the DRIV method

- Loss function for final estimate satisfies **Neyman orthogonality**⁴
- Mean-Squared-Error of final $\theta(X)$ robust to errors in auxiliary Classifications/ Regressions
- Approach extends beyond recommendation A/B tests, to linear-in-treatment IV setting
- When (6) supports CI construction, Neyman orthogonality typically preserves the validity of the intervals

ment Effect Estimation

$$X) - \mathbb{P}(T = 1 | Z = 0, X)$$

$$X) - \mathbb{P}(T = 1 | Z = 0, X)$$

$$X) \cdot \tilde{Z} = Z - \mathbb{E}[Z | X]$$

$$X) \cdot \Delta(X) ^{2}$$

$$(3)$$

$$(4)$$

$$(5)$$

$$\left(\frac{1}{T} - \theta(X) \right)^2$$

s in (1)-(2),
$$\theta(X)$$
 is given by:
 $\frac{\tilde{T}}{\tilde{Z}} - \theta(X)$

the compliance score³.

PS

Fig. 1: Example of DRIV estimates and confidence intervals for synthetic data with a step treatment effect.

The x and y axes represent the feature of heterogeneity and the treatment effect, respectively.

The shaded region depicts the 95% confidence intervals which attain ~95% coverage in Monte Carlo experiments.
